IMPACT OF FINANCIAL CRISIS ON STOCK RETURNS: EVIDENCE FROM SINGAPORE

ALAM Nafis

TAN Ee Chain

Abstract:
This paper investigates the role of macroeconomic factors and firm characteristics in explaining stock return in Singapore. The factors model is employed for two time intervals, namely, sub-period A (from July 2003 to June 2007) and sub-period B (from July 2007 to June 2011) to examine the changes in pre and post Global Financial Crisis of 2007. Our empirical findings showed that the significance relationship between macroeconomic variables and portfolio stock returns were not consistent for both sub-periods. The result is highly dependent on portfolio and sub-period.

Key words: Stock Returns; Firm Characteristics, Macroeconomic Variables; Financial Crisis

1. Introduction

Over the years, researchers, economists and financial analysts have tried to use different types of information to explain stock market return, for example, the change in economic and financial factors have been commonly used to explain the behaviour of different stock markets around the world. As suggested by economic theory, the stock price should reflect the expectation of corporate performance, while corporate profit should reflect the level of economic activities. If the theory that the stock price reflects all the fundamental economic factors (macroeconomic and financial) is true, then the stock market should be able to be utilized as a leading indicator for current as well as future economic activities. In addition, the stock market has been seen as the major driver for economic growth and plays a significant role in allocation of economic resources into the productive activities of the economy in both emerging and developed countries (Sudhahar & Raja, 2010). So, the role of the stock market has made a significant area of research on the relationship between macroeconomic factor, financial factors and the stock return. Moreover, it is envisaged
that this study could be a good reference for policy makers wishing to develop and make decisions regarding their nation’s macroeconomics policy without fear of influencing capital formation and the stock trading process.

Many studies have documented the relationship between macroeconomic variables and stock returns. Some of these studies have examined this relationship for developed markets such as USA, Japan and Europe (Chen, Roll and Ross (1986), Chen (1991), Clare and Thomas (1994), Mukherjee and Naka (1995), Gjerde and Saettem (1999), Flannery and Protopapadakis (2002)). On the other hand, some other studies investigated the situation for developing markets, particularly in the East Asia (Bailey and Chung (1996), Mookerjee and Yu (1997), Kwon and Shin (1999), Ibrahim and Aziz (2003)). There are also studies that compare the phenomenon for group of countries (Cheung and Ng (1998), Bilson, Brailsford and Hooper (2001), Wongbangpo and Sharma (2002)). These studies have provided different results. The results have changed according to the macroeconomic factors used, the research methodology employed and the countries examined. However, the studies were mainly focussed on one time series. There is not too much work done on testing the relationship during pre and post financial crisis period.

In this study, the South East Asian Tiger Singapore has been selected for empirical study. The selection of Singapore as the test target is based on two main reasons. First, Singapore has been recognized as having impressive economic growth and a growing stock market. From 2007 until 2012, Singapore GDP Growth Rate averaged 6.14 Percent reaching an all time high of 36.4 Percent in March of 2010. Singapore also witnessed a substantial increase in market capitalisation, up 35 per cent from 2010, to reach US$521 billion in 2011. As a result, Singapore now sits in the top 20 countries as measured by market capitalisation, joining the likes of the United States, Japan and the United Kingdom.

This paper investigates the role of macroeconomics and firm specific factors in explaining the stock return for Singapore in two periods. The first period is before the 2007 global economic crisis (from July 2003 to June 2007) and the second period is during and after the global economic crisis (from July 2007 to June 2011). Ordinary Least Square (OLS) multi-regression models are deployed, following the previous studies by Barrow and Naka (1994), Chen, Kim and Kim (2005), Chiang and Kee (2009). The present study employs growth rate of industrial production, change in consumer price index, growth rate of the money supply, change in the exchange rate, change in term structure and growth rate of international crude oil price as the macroeconomic factors for the time period July 2003 to June 2011. Most of the previous studies investigate the macroeconomic factor and stock return based on the main index. However, our analysis is based on stock portfolio returns rather than the stock indices return. In portfolio construction, three firm characteristics are identified to be the portfolio criteria, namely, price-to-earnings ratio, market equity and book-to-market ratio. Furthermore, the different portfolios enable us to present a cross-sectional view of the overall stock market in Singapore.
The rest of the paper is organized as follows. Section 2 reviews the related literature. Section 3 explains the data and the methodology while section 4 provides the empirical results and finally conclusion is presented in Section 5.

2. Literature Review

Due to criticism CAPM in late 1970s and subsequent drawbacks of APT in 1980s led to development of macroeconomic factor model to test the stock market performance. In the macroeconomic factor model, the factors are defined based on economic intuition and external sources information such as macroeconomic variables are used as the factors. The estimated factor loadings are verified by using time series regression whether macroeconomic variables describe the cross-sectional variations in estimated expected return. The APT macroeconomic factors model can be written as follows:

\[
\bar{E} = \alpha + \beta_{\text{Macro1}} \cdot \text{Macro1} + \beta_{\text{Macro2}} \cdot \text{Macro2} + \ldots + \beta_{\text{MacroK}} \cdot \text{MacroK} + \epsilon
\]

Where \( \bar{E} \) = expected return of the asset
\( \alpha \) = constant
\( \beta_{\text{MacroK}} \) = loading on the macroeconomic variables to k\text{th} number of factors
\( \text{MacroK} \) = risk premium for the macroeconomic variables
\( \epsilon \) = idiosyncratic error term

Based on this perspective, Chan, Chen and Hsieh (1985) analysed the macroeconomic variables together with the size effect while Chen, Roll and Ross (1986) attempted to identify the significant macroeconomic variables which influence asset return. Their tests were conducted by using the two-step procedure of Fama and MacBeth (1973), where the factor betas are estimated via time-series regression of asset return relative to the time series factor return. The macroeconomic factor models in both studies utilize number of factors such as industrial production, inflation, real interest rate, term structure, oil price and risk premium. From their studies, industrial production, risk premium and term structure were found to be significant factors influencing stock return, while the inflation effect is rather weak.

Following these initial studies, other researchers proposed various macroeconomic variables for different countries: Japan – Hamao (1988), UK – Priestley (1996), Singapore – Maysami et al. (2004), Malaysia – Ibrahim and Abdul Rahman (2003), Thailand – Tangjitprom (2011), Philippines – Bailey and Chung (1996), and the literature in this area continues to grow.

Several macroeconomic variables were used in past studies and found to have significant impact on stock returns. For instance, studies by Mukherjee and Naka (1995) for Japan, Maysami, Howe and Hamzah (2004) for Singapore, Ratanapakorn and Sharma (2007) for the US S&P500 and Humpe and Macmillan (2007) for US and...
Japan indicate that industrial production is a significant factor and is positively correlated with stock return. For exchange rate impact, results were mixed. Mukherjee and Naka (1995) and Ratanapakorn and Sharma (2007) show that exchange rate is statistically significant and positively correlated with stock return in both Japan and the US. However, there was evidence of negative correlation for stock price and exchange rate in the case of Indonesia (Rahajeng & Akhsyim, 2010), Malaysia (Ibrahim & Yosoff, 2001), Taiwan (Singh, Mehta and Varsha, 2010) and Turkey (Buyuksalvarci, 2010).

In case of money supply, most of the studies show that there is a positive correlation between money supply and stock return (Maysami, Howe and Hamzah, 2004; Ratanapakorn and Sharma, 2007; Mukherjee and Naka, 1995). Theory always states that inflation negatively related with stock price and most of the studies support the theoretical findings, for instance in the case of Japan (Mukherjee & Naka, 1995; Humpe & Macmillan, 2007), Taiwan (Singh, Mehta & Varsha, 2010), and the US (Humpe & Macmillan, 2007). However, the study by Maysami, Howe and Hamzah (2004) shows a positive relationship in the case of Singapore and the study by Chen, Roll and Ross (1986) found that inflation is weakly significant in their study on the NYSE from 1958 to 1984.

Term structure, which is derived from difference between long-term and short-term interest rate tend to be negatively correlated with stock return. The study of Stock and Watson (1989), Davis and Henry (1994) and Plosser and Rowenhorst (1994) indicates that term structure is more superior in predicting the future real economic activity than short-term interest rate in the US and European countries. The study of Chen, Roll and Ross (1986) indicates that term structure is negatively correlated with stock return in US stock exchange. Hamao (1988) indicates that the same correlation in Japan stock market.

There is no direct theory to describe the effect of oil price on stock price. However, based on the hypothesis, the oil price is a principal factor which could impact the profitability and revenue of a company and subsequently stock returns. The study by Chen, Roll and Ross (1986) found no significant oil price effect on stock return. Moreover, Al-Fayoumi’s (2009) study on the oil-importing countries found no significant relationship between oil price and stock return. However, the study by Narayan and Sharma (2011) shows that there are certain effects of the oil price on firm return and the stronger evidence can be found based on different firm size. On the other hand, the study by Le and Chang (2011) shows that for the period from 1986 to 2011 the stock market responds positively in Japan and negatively in Malaysia and an inefficient stock market responds slower to the shock of oil price.

In another extension of factor model, Fama and French (1992, 1993, 1996) designed a two-stage method to estimate the characteristic-based factor model. In the first stage, the returns of assets are sorted according to the portfolio based on the firm characteristic, such as book-to-market and market capitalization. In the second stage, the factor betas of the portfolio are estimated by time series regression of the asset return.
The Fama and French three-factor model has gained support from a number of empirical studies. For instance, Maroney and Protopapadakis (2002), Faff (2001), Drew and Veeraraghavan (2002, 2003a, 2003b) and Gaunt (2004) show the strong relationship between stock return and book-to-market equity and size in countries with different market structures such as Australia, Canada, Germany, France, Japan, the UK, the US, Malaysia, China, Hong Kong and the Philippines.

The objective of sorting the portfolio return based on firm characteristics such as price-to-earning (PE) ratio, book-to-market (BM) ratio and market equity (ME) is to further evaluate the impact of firm-specific factors on stock return as well as the interaction between different firm-specific factors and macroeconomic factors. As shown in Table 1, there are evidence of relationship between the firm-specific factor and stock return. In general, the small size portfolio (low ME) outperform large size portfolio (high ME) in term of stock return; High BM portfolio outperform low BM portfolio in term of stock return; Low PE portfolio outperform high PE portfolio in term of stock return.

3. Data & Methodology

In this paper, the analysis is conducted based on monthly time series data from July 2003 to June 2011. The data is divided into two categories. The first data set consists of macroeconomic variables while the second data set consists of stock market data.

In the first data set, seven macroeconomic variables namely growth rate of industrial production, changes in money supply (M1 and M2), change in consumer price index as the proxy of inflation, change in exchange rate, change in term structure, and growth rate of crude oil price were obtained on monthly basis from the International Financial Statistics (IFS) in International Monetary Fund (IMF) website. The monthly oil price data is obtained from the Organization of Petroleum Exporting Countries (OPEC).

In the second dataset, book-to-market equity and market capitalization are used to establish the portfolio for the stock return by grouping them into low, medium and high equity firm-specific factors. To match the variables of firms’ characteristics with stock returns, we match the accounting data for fiscal year end t-1 with the stock return of July of year t to June of year t+1. The objective in choosing a six months’ gap between fiscal year-end is to provide a conservative time for firm to release their accounting information to the public after fiscal year end t-1. The sorted stock returns are grouped into a stock portfolio based on firm characteristics. To avoid missing observations and any biases in the data sets which could potentially affect the study results, we established three criteria for stock selection. (i) The stock should not have negative book equity at fiscal year-end t-1 (Fama & French, 1995), (ii) Any stock without a trading record for more than one month will be excluded from the study and (iii) To keep the portfolio consistent, the portfolio only includes stock which was consistently traded during the eight-year period under study.

For all firms in the sampling period, three equal groups of portfolio are formed according the firm characteristics of Price-earnings (PE) ratio, book-to-market (BM) ratio and market equity (ME). The portfolios are grouped into high, medium and low based on the rank in each firm characteristic. Eventually, nine portfolios (3 portfolios x 3 firm-specific criteria) are established for the time interval July 2003 to June 2011. The data definition, symbol, source of the basic series and derived series of data and portfolio construction are illustrated in Table 2.

Source: IFS - IMF International Financial Statistic, CEIC & OPEC - Organisation of the Petroleum Exporting Countries, Bloomberg. All variables are converted into logarithm and $\Delta$ denotes the first difference for the variables.

The economic variables are transformed into natural logarithms and their first differences to achieve stationary in data to prevent spurious regression (Mukherjee & Naka, 1995; Maysami & Koh, 2004). Moreover, a natural logarithm helps in reducing the heteroscedasticity in the model. Using the state variable as derived above, the stock portfolio return model can be formed as follows:

Equation 2

$$ E = a + \beta_{2\Delta IP} IP + \beta_{2\Delta INF} INF + \beta_{2\Delta ER} ER + \beta_{2\Delta AS} AS + \beta_{2\Delta IR} IR + \beta_{2\Delta MS} MS + \beta_{2\Delta OP} OP + \epsilon $$

where the betas ($\beta$) are the loading coefficient for the state variables, $E$ represents the stock portfolio return, $a$ represents the constant term and $\epsilon$ represents the error term.

In order to estimate the regression models stated above, stationarity of the series should be examined. In this study, Augmented Dickey-Fuller (ADF) (Dickey and Fuller, 1979) test is used for testing the presence of unit roots. Two assumptions should be checked when estimating a regression model. These assumptions are independency and homoscedasticity of residual errors. Existence of serial correlation is checked by Breusch-Godfrey Langrange Multiplier test (Breusch, 1978; Godfrey, 1978). Presence of heteroscedasticity is tested by White General Heteroscedasticity Test (White, 1980). The regressions are performed by ordinary least squares (OLS) method.

4. Empirical Results

First we examined the descriptive statistics for each variable and portfolio for Singapore. Summary statistics are divided into two sub-periods, pre-crisis period (from July 2003 to June 2007) as sub-period A and during and after the crisis period (from July 2007 to June 2011) as sub-period B.
Table 3 provides the summary statistics for the state variables and stock returns of each portfolio for Singapore. The mean and standard deviation for ΔTS show significant changes from -0.02333 to 0.02813 and from 0.2623 to 0.2999 for sub-period A and sub-period B, respectively. The overall portfolio return shows that the mean monthly stock return for all portfolios in sub-period A (ranging from 1.81% to 2.69%) is higher than in sub-period B (ranging from -0.4% to 1.17%). The high BM portfolio outperforms the low and medium BM portfolios in both sub-periods.

Our findings consistently show that, on average, stock returns with high BM outperform those with low and medium BM in both sub-periods in the analysis. This result is consistent with the findings in the literature, for instance Fama and French (1992) and Barber and Lyon (1997), provided evidence that a high BM portfolio outperforms in terms of the average stock return relative to the low BM portfolio in the US stock market, while Cotter and Donnellit (2006) show the same correlation in the UK stock market. Likewise, in the Asia region, Chui and Wei’s (1998) study indicates the same correlation for Hong Kong, South Korea and Malaysia, and Chan, Hamao and Lakonishok (1991) obtain the same findings in their study on Japan.

The PE portfolio provides mixed findings on average stock return during our study period. The low PE portfolio shows higher average return in Singapore for sub-periods B. This result is similar to that of Basu (1977) and Ball (1978). Truong (2009) suggested that part of this phenomenon can be explained by investors’ erroneous extrapolation of their past performance and that the market corrects itself with new...
information that sheds light on incorrect expectations. Moreover, Truong (2009) suggests that low PE stock is low risk and low beta, but this stock more attractive than bonds. This could explain why low PE stocks become more attractive during crisis periods because other than bonds, the low PE portfolio is characterized as a “safe haven” during crisis periods. In contrast, medium and high PE portfolios shows higher average return than low PE portfolios for Singapore during sub-period A, which is in line with the findings of Lakonishok et al. (1994), who suggest that the high PE portfolios outperform in the past and are expected to continue to perform well and, vice versa, for low PE portfolios.

Size effect (ME) plays an important role in the value of stock return. Based on the findings of Banz (1981) and Reinganum (1981), low ME portfolio should outperform the high ME portfolio. Our study shows in Singapore, a developed economy, the low ME portfolio outperforms the high and medium portfolios during sub-period A, but the high ME portfolio has higher average return than the medium and low ME portfolios during sub-period B. The study of Brown, Kleidon and Marsh (1983) acknowledges that size effect is not stable over time periods.

ADF test concluded that all of the series are stationary; the effect of macroeconomic variables on the portfolio returns is then examined by OLS estimation. OLS estimation results are reported in Table 4.

Table 4 results shows that for Singapore in sub-period A, change in exchange rate, $\Delta ER$, has a significant effect on a number of portfolios in our analysis. From our regression results, it can be seen that $\Delta ER$ shows significant negative correlation for the PEM, PEL, BMM and MEH portfolios. The negative correlation indicates that the appreciation in the Singapore dollar leads to a positive effect on stock return. This result is in line with the findings of Maysami and Koh (2000) and Maysami, Howe and Hamzah (2004). They explain that Singapore is a high import and export country and appreciation in the currency enables the country to access lower-priced imported raw material, which allows domestic producers to be more competitive in the international arena in turn attract more investor and thus increase in stock price. Sub-period A further highlight that MEL portfolio is positively correlated to term structure, $\Delta TS$. This positive correlation finding is different from Chen, Roll and Ross (1986). However, Canova and DeNicolo (2000) explain that term structure is related to the future development of the economy and a steeper term structure curve is associated with higher growth of the industrial sector and lower inflation. High growth of the industrial sector and low inflation are perceived as favourable news in the stock market and thus generate a positive shock to the stock market return.

In the case of sub-period B, change in oil price, $\Delta OP$, has significant effect on most of the portfolios in Singapore. Portfolios PEH, PEM, BMH, BML, MEM and MEL are positively correlated with $\Delta OP$, which further substantiate that the overall Singapore market is responsive to the effect of $\Delta OP$. From the analysis, it is observed that $\Delta OP$ became significant during the crisis and post-crisis period. Le and Chang (2011) explain that the rising crude oil price is reflected in the stronger business performance
which results in increasing oil demand, and that this normally happens when the economy is recovering from recession – when there is high demand for oil for economic expansion. In their study of the situation in Japan, based on monthly data from 1986 to 2011, they found that the Japanese stock market responds positively in these circumstances. Furthermore, Mohan and Harminder (2011) show the same correlation for China which they state is due to the aggregate demand side for oil, which increased the oil price, during economic expansion. The aggregate demand for oil could be due to a combination of economic stimulus events in most countries, as well as in Singapore, during and post crisis. A stimulus event is denoted as favourable news because it is perceived as being a positive move to encourage real economic activities. Hence, there is a consequent increase in stock return. Assuming that past trend continues, the positive correlation between oil price and stock return may provide an effective hedge during oil price hikes.

5. Conclusion

A large number of previous studies show that there is a relationship between macroeconomic variables and stock return. These studies have provided different findings due to the different periods covered, time spans, macroeconomic factors, methodologies and countries examined. This paper extends the literature by considering the effect of firm characteristics to examine a cross-sectional view of the stock markets in Singapore. Moreover, two sub-periods were analysed to examine the relationship between macroeconomic variables and different portfolios in different sub-periods. As mentioned in the study of Erdogan and Ozlale (2005), the relationship between macroeconomic variables and stock return has not been consistent over time due to structural change.

Our empirical findings showed that the significance relationship between macroeconomic variables and portfolio stock returns were not consistent for both sub-periods. Results are highly dependent on portfolio and sub-period in our analysis. During pre-crisis period (sub-period A), portfolios in Singapore showed a significant
relationship with and . On the other hand, during crisis and post crisis period (sub-period B), portfolios in Singapore showed a significant relationship with 

In conclusion, the results indicate that macroeconomic factors have significance effect in Singapore stock market. However, each factor may react differently based on different portfolios and different sub-periods. For instance, the result shows that appreciate in currency in Singapore provides better stock return in return; During the crisis and post crisis period(sub-period B), the stock markets of Singapore are more reactive to the change in oil price. All these findings can be served as good reference for the researchers in their future development in the asset valuation area.

Based on the findings presented here, there are a number of future research directions that could be taken. For instance, further studies could consider other macroeconomic variables such as balance of trade account and government budget (budget surplus or deficit) as well as firm characteristics such as volatility factor and cash flow to price ratio to further evaluate the situation in Singapore, by using the same model. In conclusion, it is hoped that this paper will be of benefit to policy maker, stock investors and contribute to the financial literature.
